

(a) Adjusted risk ratio $1.72\times$ [1.66, 1.80]

standardized by length and cancer-detection breadth; 95% CI from 22,765 source-gene clusters (the observations are clustered, so a two-proportion z-test would not be valid). Dividing the two bars above directly gives the crude ratio ($2.45\times$), not the adjusted estimate. Length-only standardization gives $2.42\times$.

(b) 12.6% of the catalogue, co-occurrence needs no external reference

canonical-compatible AND already in the atlas's own normal-tissue export (22,003)
remainder of the catalogue (152,462)
